SPATIOTEMPORAL PATTERNS IN THE DISTRIBUTION AND ABUNDANCE OF THE
INTRODUCED REDBREAST SUNFISH (*LEPOMIS AURITUS*) AND NATIVE
LONGEAR SUNFISH (*L. MEGALOTIS*; CENTRARCHIDAE) IN
RESERVOIRS OF THE TENNESSEE RIVER DRAINAGE

By

Lacey Michelle Genard

A Thesis Submitted to the Faculty of the
University of Tennessee at Chattanooga
in Partial Fulfillment of the Requirements of the
Degree of Master of Science: Environmental Science

The University of Tennessee at Chattanooga
Chattanooga, Tennessee

May 2014
The Redbreast Sunfish (*Lepomis auritus*) was introduced in the Tennessee River drainage (TRD) in the 1940s, and contemporary anecdotal evidence suggests that *L. auritus* is possibly displacing the native Longear Sunfish (*Lepomis megalotis*). This study aimed to characterize temporal patterns in regional abundances of *L. auritus* and *L. megalotis* populations in the TRD based on a multiyear analysis of historical and contemporary fish assemblage datasets (percent abundance, density, biomass). Results indicate that *L. megalotis* abundance declined in reservoirs where *L. auritus* was found in high or increasing abundances. Also, *L. auritus* surpassed *L. megalotis* in mean percent abundance in Nickajack-Chickamauga River section and has consequently shifted *Lepomis* species composition. Although it is difficult to isolate causal variables, the interaction of both biotic (i.e., *L. auritus* competition) and abiotic (i.e., geographic variables, land use, and water quality) factors likely explain the changes in *L. megalotis* abundance and variability within river sections.
DEDICATION

This thesis is dedicated to my mother, Carla Moore Pugh. She has been an outstanding role model and has taught me the value of hard work and perseverance. I greatly appreciate her constant support throughout this process.
ACKNOWLEDGMENTS

First, I would like to express my gratitude to Dr. Mark S. Schorr for working as my thesis advisor and for giving me this opportunity. His continuous guidance and assistance throughout my time at the University of Tennessee at Chattanooga is greatly appreciated, and his mentorship has enhanced my growth as a researcher and biologist. I would also like to express gratitude to Andy Carroll for his guidance with GIS and development of range maps. Further, I wish to thank the remainder of my thesis committee, Dr. Jose Barbosa, Dr. Sean Richards, and Charles Saylor for their helpful comments and guidance. To the Biological and Environmental Science Department at the University of Tennessee at Chattanooga, thank you for making this project possible through research and teaching assistantships. To the Tennessee Valley Authority, thank you for providing fish assemblage data for analysis. Lastly, I would like to thank my family and friends for their constant support and encouragement throughout this process.

CHAPTER 1
INTRODUCTION

Impacts of Nonnative Fishes

Nonnative fishes are the most documented invaders of aquatic ecosystems, and occurrences of introductions are continuing to increase (Gozlan et al. 2010). Consequently, nonnative fishes is one of the primary causes of endangerment to riverine fish species (Dudgeon et al. 2006, Gozlan et al. 2010); they have altered aquatic communities and contributed to the worldwide decline of native fishes by lowering biodiversity, impacting ecosystem function, and causing extinction of some native species (Deacon et al. 1964, Adams et al. 2001, Byers et al. 2002, Marchetti et al. 2004, Pimentel et. al. 2005, Moyle and Marchetti 2006, Sanderson et al. 2009). In North America, nonnative fishes are a contributing factor in 67.5% of the continental fish extinctions (27 of 40 species in the last 100 years; Sanderson et al. 2009). Moreover, in the United States, nonnative fishes are a contributing factor in the listing of 70% the native fishes that are registered as threatened or endangered by the United States Fish and Wildlife Service (U.S. Endangered Species Act 1973; Rahel 2000, Clavero and Garcia-Berthou 2006).

Impacts of nonnative fishes on native ichthyofaunas may occur at the population, community, and ecosystem levels. Population-level effects may include competition for food or habitat, predation, disease, and hybridization (Flecker and Townsend 1994, Gozlan et al. 2010, Seegert 2010, Cucherousset and Olden 2011, Idelberger et al. 2011). For instance, Marsh and Douglas (1997) found that predation by introduced fishes can affect native fish species by
decreasing population numbers and reducing recruitment. At the community level, nonnative species can impact native communities by biotic homogenization, which typically involves the disappearance of many native and endemic species and the spread of nonnative species (Marsh-Matthews and Matthews 2000, Clavero and Garcia-Berthou 2006). Additionally, a review by Ross (1991) concluded that 77% of the 31 studies examined found a decline in native fish species after the introduction of nonnative fishes. Ecosystem-level effects may include habitat degradation (e.g., decreasing aquatic vegetation) and trophic-level alterations (e.g., niche shifts and cascade effects) as well as drastic ecosystem property alterations such as changes in nutrients (Flecker and Townsend 1994, Gozlan et al. 2010, Cucherousset and Olden 2011).

Anthropogenic mechanisms of the introduction of nonnative species include intentional introductions such as food aquaculture, aquarium releases, biological control, and fisheries stockings as well as unintentional introductions such as ballast water transfers, interbasin water transfers, and escape from aquaculture installations (Bunn and Arthington 2002, Marchetti et al. 2004, Gozlan et al. 2010). In the United States, the main method of introduction of nonnative fishes is intentional stocking followed by bait/aquarium release and aquaculture (USGS 2014). Although it is difficult to isolate causal variables, expansion of nonnative species in freshwater ecosystems has been linked to urbanization, agriculture, and other landscape and hydrologic alterations such as impoundments (Wilcove et al. 1998, Gido and Brown 1999, Rahel 2000, Bunn and Arthington 2002, Gido et al. 2004, Gozlan et al. 2010). Prevalence and success of nonnative fish introductions is often correlated with low native species diversity (Gido and Brown 1999, Tsunoda and Mitsuo 2012) and large rivers with dense fish populations (Gido et al. 2004, Smith et al. 2004).
Species Distributions

Mechanisms determining the distribution of fishes are complex and often not understood (Tonn et al. 1990). They occur on local and regional scales, with biotic (e.g., competition and predation) and abiotic (e.g., habitat use, morphological features, and water quality) influences (Jackson et al. 2001, Pombo et al. 2005). Water quality parameters such as dissolved oxygen, temperature, salinity, and pH in addition to other abiotic factors such as precipitation, groundwater inflow, and morphological features (e.g., disturbance, vegetative cover, and depth) are strongly related to fish community composition (Matthews et al. 1992, Jackson et al. 2001). Anthropogenic influences such as historical and current land use (e.g., urbanization, residential development, and agriculture) as well as altered flow (e.g., impoundments) are contributing factors in the occurrence, distribution, and composition of fishes (Marchetti and Moyle 2001, Bunn and Arthington 2002, Wenger et al. 2008). Species co-occurrence is also driven by abiotic factors (Tonn et al. 1990, Peres-Neto 2004) as well as biotic factors (e.g., interspecific competition and predation; Matthews et al. 1992, Winston 1995, Persson 1996, Jackson et al. 2001). Gatz (1979) found that percentage of overlap in coexisting species is half as much in nature compared to the amount of overlap possible; this pattern could be due to competition between species, forcing them into separate ecological niches.

Tennessee River Fishes

The Tennessee River drainage (TRD; total watershed area = 105,000 km²), which encompasses portions of Virginia, North Carolina, Georgia, Tennessee, Alabama, Mississippi, and Kentucky, supports 28 families encompassing an estimated total of 282 fish species (247 natives; Etnier and Starnes 1993, TVA unpublished data). Presently, in the TRD, there are 35
nonnative fish species representing 11 families: Clupeidae (2 species), Cyprinidae (12), Ictaluridae (4), Poeciliidae (1), Esocidae (2), Salmonidae (4), Gasterosteidae (1), Belonidae (1), Moronidae (3), Centrarchidae (4), and Percidae (1; Etnier and Starnes 1993, TVA unpublished data).

The Sunfishes (Centrarchidae)

The family Centrarchidae (sunfishes; 31 species), endemic to North America, includes several popular sports fishes such as the rockbasses (*Ambloplites* spp.), black basses (*Micropterus* spp.), crappies (*Pomoxis* spp.), and others collectively known as bream (*Lepomis* spp.). Centrarchids have been widely introduced around the world, often in lakes and rivers where they become invasive (Cucherousset and Olden 2011). In North America, many sunfish species have been released or stocked outside their natural ranges and have negatively impacted other species, even their congeners (Huckins *et al.* 2000). However, relatively few studies have measured their impacts on native fishes, particularly on native congeneric sunfishes (Etnier and Starnes 1993).

In the TRD, there are five genera and 19 species of centrarchids (15 natives and 4 nonnatives; Etnier and Starnes 1993). Nonnative centrarchids in the TRD include Redbreast Sunfish (*Lepomis auritus*), Pumpkinseed (*L. gibbosus*), Redeye Bass (*Micropterus coosae*), and Alabama Spotted Bass (*Micropterus henshalli*). Of these, the Redbreast Sunfish (*Lepomis auritus*) is one of the most abundant and widespread nonnative species in streams and reservoirs of the TRD (TVA unpublished data).
Redbreast Sunfish (Lepomis auritus)

*Lepomis auritus* is native to the Atlantic Slope (New Brunswick to central Florida) and Gulf slope drainages, and west to Apalachicola and Choctawhatchee drainages (parts of Alabama, Florida, and Georgia); populations outside of this area are considered introduced (Etnier and Starnes 1993, Boschung and Mayden 2004, Page and Burr 2011). The mechanism of introduction into the TRD is most likely due to intentional stocking for sport fishing (USGS 2014). The first recorded occurrences of *L. auritus* in the Tennessee River drainage date back to the early 1940s in tributary streams of Watts Bar and Fort Loudoun reservoirs in eastern Tennessee (TVA unpublished data). *L. auritus* is now well established in the upper Tennessee River drainage downstream to the Chattanooga area; expanding populations of *L. auritus* appear to correspond with decreasing numbers of the native Longear Sunfish (*Lepomis megalotis*), an ecologically similar species (Etnier and Starnes 1993, Boschung and Mayden 2004).

*L. auritus* is highly adaptable to a variety of habitats such as lakes, reservoirs, swamps, and backwaters; however, it prefers rocky or sandy pools of streams and rivers (Aho *et al.* 1986, Etnier and Starnes 1993, Boschung and Mayden 2004, Page and Burr 2011). Primarily an insectivore, *L. auritus* feeds on aquatic invertebrates (e.g., amphipods), nymphal stages of aquatic insects (e.g., trichopterans), and terrestrial insects (Davis 1972, Bass and Hitt 1974, Sandow *et al.* 1974, Etnier and Starnes 1993, Boschung and Mayden 2004, Gautreau and Curry 2012); it is also known to consume crayfish and small fishes (Etnier and Starnes 1993). Juveniles up to 100 mm feed heavily on ostracods, chironomids, and dipteran larvae (Etnier and Starnes 1993, Boschung and Mayden 2004). However, diet is variable and is determined by prey availability and size (Aho *et al.* 1986). A tolerant species, *L. auritus* can withstand moderate
turbidity (< 100 JTU’s) and high water temperatures (33-39 °C), but often move to more suitable habitat if it is accessible (Aho et al. 1986, Sandow et al. 1974, Jenkins and Burkhead 1994).

The spawning season of L. auritus occurs April through August, and activity is greatest during June; nest building begins in springtime when waters reach 16-21°C (Etnier and Starnes 1993, Boschung and Mayden 2004, Gautreau and Curry 2012). Spawning occurs at water temperatures ranging from 16.8-25.6 °C (Davis 1972, Bass and Hitt 1975). Nests are usually solitary and are constructed in sandy substrate or sometimes over a vegetative mat. They are located within shallow portions (< 1.5 m) of streams that have low, stable velocities (<0.10 m/s), near the shoreline and some form of protective covering such as vegetation, submerged logs, stumps, or overhanging banks (Etnier and Starnes 1993, Lukas and Orth 1993, Boschung and Mayden 2004, Gautreau and Curry 2012). However, some nests have been found in open water or in areas with little covering (Gautreau and Curry 2012). Nests of L. auritus are typically 30-94 cm in diameter and can often be distinguished from other Lepomis species by the uniform shape of stones in the nests (≤12mm; Davis 1972, Boschung and Mayden 2004). Most other species of Lepomis typically make sounds during courtship and spawning; L. auritus is usually silent which can also serve as a type of species recognition (Gerald 1971, Etnier and Starnes 1993, Boschung and Mayden 2004). In females, fecundity increases greatly with size and averages approximately 3,300 eggs per female with a range of 322-9,206 eggs (Sandow et al. 1975, Etnier and Starnes 1993). Males guard nests of fertilized eggs until they are hatched, usually 7-10 days following fertilization (Gautreau and Curry 2012).
Longear Sunfish (*Lepomis megalotis*)

*Lepomis megalotis* is native to the southern portion of the Hudson Bay drainage, Mississippi River basin, tributaries to three of the Laurentian Great Lakes (Huron, Michigan, and Erie), Gulf Slope drainages (Apalachicola River through the Rio Grande drainage in Mexico), and the Tennessee River drainage (Etnier and Starnes 1993). It is widely distributed throughout the Tennessee River and its tributaries except in the highest portions of the Blue Ridge ecoregion; however, *L. megalotis* is much less common in the upper portion of the TRD where it is broadly sympatric with the ecologically similar redbreast sunfish (Etnier and Starnes 1993). There are several subspecies of *L. megalotis* within its native range, such as the Northern Longear Sunfish (*Lepomis megalotis peltastes*) and the Central Longear Sunfish (*Lepomis megalotis megalotis*; Jennings and Phillip 1992). *L. m. megalotis* is present throughout the Tennessee River drainage (Bauer, University of Tennessee unpublished data).

Preferred habitat of *L. megalotis* is rocky or sandy-bottomed pools of moderately flowing headwater and medium-sized streams (Etnier and Starnes 1993, Boschung and Mayden 2004). It is also associated with margins near vegetative cover, undercut banks, logs, or brush. *L. megalotis* is adapted well to pools and reservoirs of major rivers as well as brackish waters of coastal streams (Etnier and Starnes 1993, Boschung and Mayden 2004). Although *L. megalotis* typically stays within a very small home range, it has very strong homing capabilities by way of olfaction (Etnier and Starnes 1993, Boschung and Mayden 2004). Mainly insectivorous, adults feed on aquatic and terrestrial insects, fish eggs, and aquatic invertebrates (e.g., bryozoans); larger adults particularly feed on terrestrial insects and often feed on the surface of the water. Juveniles feed mainly on microcrustaceans and aquatic insects (Etnier and Starnes 1993,
Boschung and Mayden 2004). Although considered secure throughout its range (Boschung and Mayden 2004), *L. megalotis* is categorized as intolerant and can be susceptible to environmental stressors such as water quality degradation (Jennings 2013, TVA unpublished data).

Spawning mainly occurs May through August once nest-building activity is triggered by warmer water (≥25 °C) and a longer photoperiod (16 hours; Boschung and Mayden 2004). Nests are constructed close together in colonies along shorelines over gravel substrate; solitary nests are occasionally found near colonies of nests (Etnier and Starnes 1993, Boschung and Mayden 2004). Males diligently guard nests while females are able to spawn in the nests of several males (Etnier and Starnes 1993, Boschung and Mayden 2004). Although *L. megalotis* does not exhibit female mimicry like some other *Lepomis* species, smaller males sometimes dart into nests and attempt to fertilize the eggs while a nuptial pair is beginning to spawn (Boschung and Mayden 2004). Sound production by way of grunting may also play a role in spawning (Gerald 1971, Boschung and Mayden 2004). Females spawn in the nests of several males, with egg production as much as 4,000 eggs per female (Etnier and Starnes 1993). After spawning, males fan fertilized eggs immediately, then alternate sweeping and fanning. The sweeping drives the eggs deeper into the protective gravel substrate, and the fanning keeps silt and other debris from settling on the developing eggs (Etnier and Starnes 1993, Boschung and Mayden 2004). Males guard and maintain nests until eggs are hatched (Etnier and Starnes 1993).

Anecdotal evidence suggests that *L. auritus* is possibly displacing native Longear Sunfish (*Lepomis megalotis*; Etnier and Starnes 1993). Cooner and Bayne (1982) reported significant overlap in the diets of *L. megalotis* and *L. auritus*, suggesting that diet may play a role in competitive interactions between sympatric populations of the two species; with the exception of
Justification for Research

Interspecific competition may play an important role in the organization of local fish communities (Jackson et al. 2001). Quantifying the distribution and abundance of an introduced fish species and native congeneric species in an aquatic system is an important first step to understanding and studying its possible interactions and effects of introduced species on native species. Understanding impacts and interactions of these species will be vital in protecting native species and preserving biodiversity in the TRD. Furthermore, scientific documentation is lacking on the introduction of *L. auritus* to the Tennessee River drainage (e.g., year, location); spatiotemporal patterns in the distribution and abundance of *L. auritus* and *L. megalotis* have not been investigated.
Research Questions

1) When and where was the Redbreast Sunfish (*Lepomis auritus*) introduced in the Tennessee River drainage (TRD)?

2) How has the distribution and abundance of *L. auritus* changed within the TRD?

3) Has *L. auritus* had an effect on the distribution and abundance of the native Longear Sunfish (*L. megalotis*) within the TRD?

4) Do electrofishing catch rates provide reliable indices of *Lepomis* sunfish density?

Research Objectives

1) Estimate the time(s) and geographic point(s) of introduction and establishment for *L. auritus* in reservoirs of the TRD.

2) Characterize temporal patterns in regional abundances of *L. auritus* and *L. megalotis* populations in the TRD based on a multiyear analysis of historical and contemporary datasets (rotenone, 1947-1997, and electrofishing/gill-netting, 1993-2012, respectively).

3) Determine whether electrofishing data provide reliable indices of population density (based on rotenone data) for *Lepomis* species in TRD reservoirs.
CHAPTER 2
METHODS

Study Area

The Tennessee River drainage (TRD; total watershed area = 105,000 km$^2$) encompasses portions of Virginia, North Carolina, Georgia, Tennessee, Alabama, Mississippi, and Kentucky (Etnier and Starnes 1993). Five major Level III ecoregions traverse the TRD: Southeastern Plains, Interior Plateau, Southwestern Appalachians, Ridge and Valley, and Blue Ridge (Figure 1).

Ecoregions of the Tennessee River Drainage

The Southeastern Plains ecoregion is part of the Coastal Plains physiographic province and covers the westernmost portion of the TRD. It extends as far north as Maryland and as far south as the Gulf of Mexico. The Southeastern Plains is characterized by irregular, flat plains including agricultural lands, forests, and some wetland areas (Sohl 2012a); natural vegetation is predominantly oak-hickory-pine, but much of that has been replaced by heavily managed timberlands (EPA 2010). Elevation is generally lower than the Interior Plateau to the east and higher than the Mississippi Alluvial Plain to the west (Sohl 2012a). The terrain consists of sands, silts, and clays (EPA 2010).

Farther east, the Interior Plateau ecoregion encompasses much of central Tennessee and northern Alabama, while extending north into parts of Indiana and Ohio. It is characterized by
rolling plains, grassland plateaus and forested uplands; natural vegetation is primarily oak-hickory forest, and it also contains fertile lowlands (EPA 2010). Elevations range from 105-410m, and it is generally lower in elevation than the Southwestern Appalachians and Blue Ridge ecoregions to the east (EPA 2010, Drummond 2012). Limestone, chert, sandstone, siltstone and shale are dominant rock types, with karst terrain being prevalent (EPA 2010). Agriculture and urbanization has impacted this area, and water quality is of concern in watersheds with significant coal mining and agriculture (Drummond 2012).

The Southwestern Appalachians ecoregion occurs in Kentucky, Tennessee, Georgia, and Alabama and borders the Interior Plateau ecoregion to the east (EPA 2010). The Southwestern Appalachians ecoregion is characterized by open low mountains with upland forests and some agricultural lands on valley floors (Sohl 2012b). Approximately 75% of the ecoregion is covered by forest, primarily oak-pine communities; however, limestone, coal, and iron deposits have resulted in significant historical mining activity (Sohl 2012b). Furthermore, the Cumberland Plateau is a significant part of the Southwestern Appalachians; this region contains conglomerate, sandstone, siltstone, and shale is covered by mostly well-drained, acidic soils of low fertility.

The Ridge and Valley ecoregion borders the Southwestern Appalachians ecoregion to the east, extends as far north as New York, and as far south as Alabama. It is characterized by roughly parallel ridges and lowland valleys with forests and some agricultural lands (Friesen and Stier 2012). Although elevations can reach up to 1500m on some ridges, it is generally lower in elevation and has less forest cover than the Blue Ridge ecoregion to the east (Friesen and Stier 2012). Forests and managed lands are the dominant land-use type, while agricultural and urban areas comprise a smaller portion of the ecoregion (30%, 9% respectively; Friesen and Stier
Due to faulting and folding, it also has a variety of geologic materials: limestone, dolomite, shale, siltstone, sandstone, chert, mudstone, and marble (EPA 2010).

The Blue Ridge ecoregion covers the easternmost part of the TRD and is located within the Southern Appalachian Mountains, extending from southern Pennsylvania to northern Georgia (EPA 2010, Taylor and Kurtz 2012). It predominantly contains Appalachian oak forests, but a variety of oak, hemlock, and pine communities occur within this forest type (EPA 2010). The terrain is characterized by narrow ridges and hilly plateaus, with elevations generally ranging from 300-1500m (EPA 2010). The ecoregion is mostly forested, with approximately 33% of publicly owned lands; however, agriculture and developed lands make up a small portion of the ecoregion (Taylor and Kurtz 2012). Metamorphic bedrock (i.e. gneiss, schist, and quartzite) is the dominant rock type, but some areas of igneous and sedimentary geology also occur.

Reservoirs of the Tennessee River Drainage

The Tennessee River is formed by the confluence of the French Broad and Holston rivers east of Knoxville, Tennessee and eventually joins the Ohio River at Paducah, Kentucky (totaling 1,426 km in length; Figure 1). The mainstem (main channel) of the Tennessee River contains a series of multipurpose impoundments that were mostly constructed in the 1930s-1960s by the Tennessee Valley Authority (TVA; Table 1). There are nine mainstem reservoirs in the Tennessee River drainage: Kentucky Reservoir, Pickwick Reservoir, Wilson Reservoir, Wheeler Reservoir, Guntersville Reservoir, Nickajack Reservoir, Chickamauga Reservoir, Watts Bar Reservoir, and Fort Loudoun Reservoir (listed in sequence from the mouth of the Tennessee River; Table 1). Although these mainstem impoundments created large reservoirs of water, they
are considered “flow through” impoundments in which the downstream flow is generally maintained (Etnier and Starnes 1993).

Kentucky Reservoir is the largest reservoir (64,922 ha) and is located near the mouth of the Tennessee River (Tennessee River km 36-333) within the Interior Plateau and Southeastern Plains ecoregions. Data were collected from eight tributary reservoirs: Redbud Reservoir (impounds Dry Creek), Sycamore Reservoir (Dry Branch Creek), Cedar Reservoir (Haley Creek), Pine Reservoir (Piney Creek), Pin Oak Reservoir (Browns Creek), Dogwood Reservoir (Big Creek), Beech Reservoir (Beech Creek), and Normandy Reservoir (Duck River).

Farther upstream, Pickwick Reservoir (TR km 333-418) is located within the Southeastern Plains ecoregion. Data were collected from four of its tributary reservoirs, which are all located within the Interior Plateau ecoregion: Little Bear Creek Reservoir (impounds Little Bear Creek), Cedar Creek Reservoir (Cedar Creek), Bear Creek Reservoir (Bear Creek), and Upper Bear Creek Reservoir (Bear Creek). Wilson (TR km 418-442) and Wheeler (TR km 442-562) reservoirs are located completely within the Interior Plateau ecoregion. Data were collected from one tributary reservoir of Wheeler Reservoir (Tims Ford Reservoir; impounds Elk River).

Guntersville Reservoir (TR km 562-684) is located within the Southwestern Appalachians ecoregion and contains no tributary reservoirs. Nickajack Reservoir (TR km 684-758) is located within the Southwestern Appalachians and Ridge and Valley Ecoregions and includes remnants of Hales Bar Reservoir. Hales Bar Dam was dismantled in 1967 and was replaced by Nickajack Dam 10.3 km downstream; therefore, data from both reservoirs were combined.
Chickamauga Reservoir (TN River km 758-853) is located within the Ridge and Valley ecoregion although most of its tributaries are within the Blue Ridge ecoregion. Data were collected from six tributary reservoirs: Parksville Reservoir (impounds Ocoee River), Nottely Reservoir (Nottely River), Blue Ridge Reservoir (Toccoa River), Appalachia Reservoir (Hiwassee River), Hiwassee Reservoir (Hiwassee River), and Chatuge Reservoir (Hiwassee River). Watts Bar (TR km 853-969) and Fort Loudoun (TR km 969) reservoirs are located in the upper portion of the TRD and are also within the Ridge and Valley ecoregion. Portions of these reservoirs are also in the Blue Ridge ecoregion and the Cumberland Plateau portion of the Southwestern Appalachians ecoregion. Data were collected from eight tributary reservoirs within Watts Bar mainstem reservoir: Santeetlah Reservoir (impounds Cheoah River), Thorpe Reservoir (West Fork Tuckasegee River), Nantahala Reservoir (Nantahala River), Melton Hill and Norris reservoirs (Clinch River), and Tellico, Cheoah, and Fontana reservoirs (Little Tennessee River). Data were collected from seven tributary reservoirs within Fort Loudoun mainstem reservoir: Douglas Reservoir (impounds French Broad River), Watauga Reservoir (Watauga River), Fort Patrick Henry, Boone, and South Holston reservoirs (South Fork Holston River), and Cherokee and John Sevier reservoirs (Holston River).

Data Acquisition

Reservoir fish assemblage data from two multiyear surveys – rotenone sampling and electrofishing/gill-net sampling – were acquired from the Tennessee Valley Authority (TVA). This study focuses on fish data collections within the Tennessee River drainage (41 reservoirs).
Rotenone Data

Cove rotenone sampling was employed by TVA (1947-1997) to collect data on fish assemblages (species composition, diversity, density, and biomass) in 41 reservoirs in the Tennessee River drainage (TRD; 9 mainstem, 32 tributaries; Table 1). One to 40 years of sample data were collected from each reservoir.

Rotenone is a natural toxicant made from the extract of *Derris* roots, which causes fish to die from asphyxiation (Baldwin *et al.* 1996). Rotenone is useful in sampling fishes along shorelines and coves in reservoirs in order to estimate population parameters. Sampling areas cannot be completely random because coves must be of suitable size and depths to hold block nets that prevent movement of fish into or out of the sampling area. Furthermore, some suitable sampling areas could not be utilized due to adjacency to houseboats, boat docks, recreational facilities, streams, or other sensitive habitat. However, sites were selected in various parts of the reservoir and were determined to be representative samples each reservoir (TVA unpublished data).

In each TVA reservoir, an enclosed area within a cove or shoreline (1-20 samples per reservoir, depending on reservoir/year; range of sampling areas = 0.18-1.68 ha) was sampled by applying rotenone to the water using standard methods (Davies and Shelton 1983). Standard sampling methods were as follows: A nylon block net, 300 feet by 25 feet by ½-inch-bar mesh was set across the open end of the sample cove the evening before or the morning prior to the rotenone treatment. Scuba divers ensured that the block net was properly placed so that it effectively blocked all fish movements. The net served as the outer boundary of the sampling area. Surface area, water volume, and maximum and average depths were calculated before treatment. Five percent emulsifiable rotenone was used at a concentration of 0.6 ppm for
samples from 1960-69 and 1.0 ppm for samples from 1970-1997; concentrations are unknown for data prior to 1960. Rotenone was first applied to the area adjacent to the block net to form a barrier against movement of small fish through the net. It was then applied to deep water by a centrifugal pump and weighted hose, and shallow surface areas were sprayed. Fishes were picked up in the sample area over a two-day period. Fishes were then sorted into species and then into 25mm size groups. Numbers and weights of each size group of each species were recorded the first day; numbers were only recorded the second day. Numbers from the first and second day were summed before density (number of fish per hectare) was calculated. Because fish picked up on day two had deteriorated slightly, calculated biomass would have been inaccurate. Therefore, total biomass was calculated by averaging weights of fishes for each size class from the first day of sampling. That information was applied to fishes from the second day (by multiplying weights of same size classes from first day by number of fishes from second day).

TVA cove rotenone sampling methodology varied between years and locations. Before 1958, the sampling area was not accurately determined using consistent methods. Also, prior to 1960, samples were taken without the use of a block net. Therefore, data collected during this time period was not suitable for calculating density and/or related parameters that require a specified sampling area. However, data collection was standardized in the southeastern United States by 1960, and most data collected during this time period is suitable for all quantitative uses.

Sunfish (Lepomis spp.) population parameters (presence/absence, percent abundance, density, biomass) were estimated for all reservoirs in the rotenone survey. Species presence/absence and percent abundance \[\{(\text{number of fish} \div \text{total number of all fishes}) \times 100\]
were determined from all years of data. However, because data quality varied among reservoirs/years, density (number of fish per hectare) and biomass (kilograms of fish per hectare) were calculated from data collected during/after 1960.

Electrofishing/Gillnetting Data

Electrofishing and gillnetting data were collected by TVA (1993-2012) as part of the Vital Signs survey to collect data on fish assemblages in 29 TRD reservoirs (9 mainstem, 20 tributaries; Table 1). Nine to nineteen years of data were collected from each reservoir. These data were used to assess reservoir health using the Reservoir Fish Assemblage Index (Hickman and Brown 2002); this multimetric ecoregion-specific index was developed by TVA in the early 1990s as a part of a monitoring program to assess reservoir health based on measurements of fish community attributes.

TVA fish sampling methods included boat electrofishing and gill netting (Hubert 1996, Reynolds 1996). Electrofishing is the use of electrical currents to capture fish in which electrical current flows between the electrodes of opposite polarity (anode and cathode), creating a three-dimensional electrical field (Reynolds 1996). In boat electrofishing, the metal hull of the boat serves as the cathode, while metal cylindrical poles extending from front of boat are used as the anode. When exposed to the electrical field, fishes exhibit behavioral responses that facilitate capture: oscillotaxis (thrashing movement), electrotaxis (forced swimming), or immobilization (Reynolds 1996). TVA fish sampling consisted of electrofishing boat runs along various types of shoreline. Fifteen sampling runs were conducted at each site (1-7 sites per reservoir, depending on reservoir/year). Each run was 30.5 meters long with duration of approximately 10-30 minutes.
Gill nets are vertical panels of netting with varying mesh sizes held vertically in water by weights and floats. Fishes are captured by the netting becoming held around the body, held behind the gills (opercula), or tangled in teeth, spines, or other protrusions (Hubert 1996). Fishes collected from both sampling techniques were identified, counted, and examined for anomalies (Baker 2011). After examining summary data, most *Lepomis* species were not captured using gill nets. Therefore, only electrofishing data were used in the analysis. Relative density of each species captured during sampling was determined by calculating the catch rate per unit effort (CPUE).

Data Analysis

Rotenone and electrofishing datasets were analyzed separately to assess spatiotemporal patterns in the distributions and abundance of introduced Redbreast Sunfish (*Lepomis auritus*), native Longear Sunfish (*L. megalotis*), and two other native congeneric sunfishes [Bluegill Sunfish (*L. macrochirus*) and Redear Sunfish (*L. microlophus*)], which served as reference species. Reference species were chosen based on their expansive distribution and moderate to high abundances throughout the TRD. Other native congeneric sunfishes that were present in most of the TRD were summarized (Appendix B.4, B.5) but not included in most of the analyses.

Young-of-year (YOY) were excluded from data summaries and analyses for both rotenone and electrofishing datasets due to high mortality rates and unstable populations of YOY; therefore data only included intermediate and adult age classes. In most reservoirs, YOY age classes were less than 75 mm in total body length (TVA unpublished data).

Various population parameters (presence/absence, percent abundance, density/CPUE, and biomass) were examined in the analysis. It is important to note that percent abundance of a
species is mathematically related to the abundances of other species. For instance, if a species maintained abundance over a period of time, and another species increased in abundance over that same period, the former would experience a decline in percent abundance due to the increase in abundance of the latter. In contrast, density/CPUE and biomass are mathematically independent of other species.

Objective 1

The first objective was to estimate the times and geographic points of introduction and establishment for *L. auritus* in reservoirs of the TRD. The United States Geological Survey (USGS) considers a nonnative species to be established if that species is reproducing and overwintering (USGS 2014). The time period during which *L. auritus* was introduced and became established in TRD reservoirs was determined by examining rotenone (1947-1997) and electrofishing (1993-2012) datasets. Year-specific data on *L. auritus* presence/absence was examined in each mainstem and tributary reservoir. Years *L. auritus* was found and first/last years detected were recorded for each reservoir; percentages of years present compared to total sampling years were also calculated for each mainstem reservoir.

Objective 2

The second objective was to characterize temporal trends in regional abundances of *L. auritus* and *L. megalotis* populations in the TRD. Mainstem reservoirs were combined into five river sections based on ecoregion, proximity, and first year of *L. auritus* appearance: Kentucky-Pickwick, Wilson-Wheeler, Guntersville, Nickajack-Chickamauga, and Watts Bar-Fort Loudoun (Figure 2). Temporal trends were analyzed for populations/assemblages of native congeneric
sunfishes (*Lepomis* spp.) in river sections with established populations of *L. auritus* (treatment) and in those without *L. auritus* (control). Historical and contemporary trends were examined using rotenone and electrofishing data, respectively. For both datasets, data were transformed to improve normality and homogeneity of variances (HOV). Percent abundance was arcsin-transformed [arcsin square root of species proportion (*p*), where *p* = number of individuals of a species / total number of individuals of all *Lepomis* sunfishes]. Density and biomass data were log-transformed [log$_{10}$ (x + 1)].

Longitudinal mixed-effects regression methods with polynomials were performed for both datasets to quantify long-term changes in *Lepomis* sunfishes in five river sections within the TRD. The mixed-effects model contained both fixed (years) and random (subjects) effects; this model more properly tests for a relationship in repeated measures designs because it accounts for residual variation as well as variation within subjects (Zar 2010). Polynomial regressions are a type of multiple linear regression that can fit nonlinear relationships and are useful for fluctuating data; they are fitted successively starting with a linear (first order) regression and increase in order (quadratic, cubic, quartic). The order with the best fit (lowest P value) is used in addition to all lower order terms (e.g. $\hat{y} = a_0 + a_1x - a_2x^2 + a_3x^3$; Zar 2010). Because sampling sites within reservoirs were considered to be spatially independent of one another (within coves/along shorelines), the sampling sites were the replications in the study (Maceina *et al.* 1994). Repeated-measures ANOVA and Dunnett’s tests were also performed for both datasets to examine changes in *Lepomis* species composition in each river section.
**Historical Trends**

Rotenone samples (1947-1997) were analyzed using longitudinal mixed-effects regression methods in order to assess temporal trends (species vs. year) for percent abundance (arcsin square root of species proportion \(p_i\), where \(p_i = \text{number of individuals of a species} / \text{total number of individuals of all } Lepomis \text{ sunfishes} \)), density \(\log_{10}(\text{fish/ha} + 1)\) and biomass \(\log_{10}(\text{kg/ha} + 1)\) of \(L. \text{ auritus}\) and selected native congeneric sunfishes (\(L. \text{ megalotis, L. macrochirus, L. microlophus}\)). Species-specific trends were analyzed in reservoirs with and without \(L. \text{ auritus}\). Data collected during or prior to 1960 was not suitable for analysis density and/or related parameters; therefore, only percent abundance was calculated using all sampling years (1947-1997). For percent abundance, sampling years were separated into two time periods: late 40s-60s and 70s-90s. Due to low data quality prior to 1960 and very few sampling years in the 1960s, density and biomass were calculated using sampling years from 1970-1997. For Kentucky-Pickwick River section, 1988 was omitted due to only one sample from that year and five years excluding it from other sampling years.

**Contemporary Trends**

Electrofishing samples (1993-2012) were used to calculate reservoir-year-specific estimates of percent abundance and relative density (catch per unit effort, CPUE) of \(L. \text{ auritus}\) and selected native congeneric sunfishes (\(L. \text{ megalotis, L. macrochirus, L. microlophus}\)). Longitudinal mixed-effects regression methods were used to assess temporal trends (species vs. year) for percent abundance (arcsin square root of species proportion \(p_i\), where \(p_i = \text{number of individuals of a species} / \text{total number of individuals of all } Lepomis \text{ sunfishes} \)) and relative density \(\log_{10}(\text{CPUE} + 1)\) of the aforementioned species. Species-specific trends were
analyzed in reservoirs with and without *L. auritus*. Data from 2012 were omitted in Nickajack-Chickamauga River section because there was only one sample from that year.

*Species Composition*

Repeated-measures ANOVA and Dunnett’s test (*α* < 0.05) were used to compare mean (arcsin√*p*) percent abundance of *L. megalotis* with other congeneric sunfishes. Dunnett’s test is a type of multiple comparison in which one sample (*L. megalotis*) is compared to all other samples (other congeneric sunfishes) to determine if their means are statistically different (Zar 2010). *L. macrochirus* is consistently the most abundant species in the TRD, so it was removed from the analysis with the exception of Kentucky-Pickwick Reservoir (1993-2011; when it was the second most abundant species).

**Objective 3**

The third objective was to determine whether electrofishing and/or gill-netting catch data provided reliable indices of population density (based on rotenone data) for *Lepomis* species in TRD reservoirs. Pearson’s linear correlation analysis was used to test the relationship between historical cove-rotenone density and electrofishing CPUE to determine if electrofishing data provide an accurate index of *Lepomis* sunfish density. Rotenone sampling obtains an accurate sample of the area because rotenone reaches all depths and affects all age/size classes; on the other hand, electrofishing may not effectively capture some fish age/size classes and certain habitats. For each reservoir (mainstem and tributary) where sampling years overlapped in both datasets, samples were averaged for each reservoir and each sampling year for six *Lepomis* species – four species previously described and two additional congeneric sunfishes (Green
Sunfish, *Lepomis cyanellus*; Warmouth Sunfish, *Lepomis gulosus*). These species typically comprise a complete assemblage of *Lepomis* species within a given reservoir in the TRD.

**Statistical Significance**

Statistical significance was declared at an alpha ($\alpha$) level of 0.05. To reduce the risk of making a type-I error, the sequential Bonferroni procedure (Rice 1989) was applied when performing multiple related statistical tests. For each type of population-level analysis within a river section (e.g., regression of species abundance vs. year), the overall alpha level was adjusted for the number of *Lepomis* species tested. For example, to test historical population trends of four *Lepomis* species within a river section, species-specific regression relationships (e.g., $y =$ percent abundance, $x =$ year) were initially tested at a Bonferroni-adjusted alpha level of 0.0125 ($0.05/4$); if the species trend with the lowest P-value was significant, then the species trend with second-lowest P-value was tested at $0.0167$ ($0.05/3$), then the species trend with third-lowest P-value was tested at $0.025$ ($0.05/2$), and so on; if a species trend was not significant, then trends with larger P-values are declared not significant (even if $P < 0.05$).

**Statistical Analysis System**

The Statistical Analysis System (SAS) is a software program developed by the SAS Institute that is used for data management and analysis. SAS programs are written in codes known as SAS language. The DATA step typically generates a SAS data set, while the PROC step analyzes the data (SAS Institute 2014). For this data analysis, data were summarized and analyzed using SAS 9.3. PROC MIXED was used to perform longitudinal regressions and repeated-measures ANOVAs.
CHAPTER 3
RESULTS

Introduction of Redbreast Sunfish (*Lepomis auritus*) into the TRD

First records of *L. auritus* in mainstem reservoirs of the Tennessee River drainage occurred in 1950 in the middle reaches of the Tennessee River (Wilson, Wheeler, and Guntersville). *L. auritus* was also detected in the upper reaches in the 1950s (Watts Bar, 1957; Fort Loudoun, 1953). *L. auritus* was not detected until the 1970s in the middle-upper reaches (Nickajack, 1972; Chickamauga, 1976). *L. auritus* was not detected in the lower reaches until the early 2000s (Kentucky, 2003; Pickwick, 2001; Figure 2).

Historical Patterns

Historical rotenone samples (1947-1997) indicated that *L. auritus* was not found in much of the western TRD (Interior Plateau and Southeastern Plains ecoregions; Table 1). It was not present in Kentucky Reservoir (sampled 22 years; 1949-1982) and only in one of eight tributary reservoirs (Piney Creek, found 1 of 2 years sampled; 1980-1984). *L. auritus* was also not detected in Pickwick Reservoir (sampled 23 years; 1949-1987) or in any of its four tributary reservoirs. *L. auritus* was first detected in 1950 in three sequentially-located mainstem reservoirs – Wilson, Wheeler, and Guntersville. Although it was detected in 1950 in Wilson Reservoir, it
was not found any other year (sampled 15 years; 1949-1983). In Wheeler Reservoir, *L. auritus* was first found in 1950 and later found in 1984 and 1995 (sampled 42 years; 1949-1997); however, it was not detected in Tims Ford Reservoir (tributary impoundment sampled 3 years; 1974-1984).

In the middle-upper TRD (Southwestern Appalachians, Ridge and Valley, and Blue Ridge ecoregions), *L. auritus* was found numerous years. Although *L. auritus* was first detected in 1950 in Guntersville Reservoir, it was not found consistently until 1986 (found 6 of 31 years; 1947-1993). *L. auritus* was never detected in Hales Bar Reservoir (sampled 7 years; 1949-1964 and dismantled in 1967), but it was found all years sampled in Nickajack Reservoir, which replaced Hales Bar Reservoir (sampled 5 years; 1972-1981). *L. auritus* was not found in Chickamauga Reservoir until 1976, but was found consistently thereafter (17 of 36 years sampled; 1947-1997). Conversely, it was first detected in two tributary reservoirs of Chickamauga in the 1950s (Nottely Reservoir, 1958; Chatuge Reservoir, 1953) and was later found in all tributary reservoirs of Chickamauga, with the exception of Parksville Reservoir. *L. auritus* was found in Watts Bar Reservoir starting in 1957 (11 of 17 years sampled; 1949-1986) and was also detected in five of the eight tributary reservoirs. The first detection of *L. auritus* in Fort Loudoun Reservoir was in 1953, and it was found consistently thereafter (10 of 13 years sampled; 1949-1993). *L. auritus* was detected in all six tributary reservoirs of Fort Loudoun.

Contemporary Patterns

Electrofishing samples (1993-2012) indicated that *L. auritus* was later detected in parts of the western TRD (Interior Plateau and Southeastern Plains ecoregions). It was found in Kentucky starting in 2003 (found 4 of 12 years sampled; 1993-2011); however, it was detected earlier
(1993) in Normandy Reservoir (1 of 11 years sampled; 1993-2011). *L. auritus* was first detected in Pickwick Reservoir in 2001 (8 of 16 years sampled; 1993-2011); however, it was found earlier in Little Bear Creek (1993) and Bear Creek (1999) tributary reservoirs. After not being detected in Wilson Reservoir since 1950, *L. auritus* resurfaced in 1996 (3 of 10 years sampled; 1993-2010). On the other hand, *L. auritus* was continually found in Wheeler Reservoir (13 of 17 years sampled; 1993-2011) and was first detected in 1993 in Tims Ford Reservoir (1 of 11 years sampled; 1993-2010). Its presence also continued in Guntersville Reservoir (14 of 15 years sampled; 1993-2011), Nickajack Reservoir (11 of 11 years sampled; 1993-2011), Chickamauga Reservoir (19 of 19 years sampled; 1993-2012), Watts Bar Reservoir (18 of 18 years sampled; 1993-2012), and Fort Loudoun Reservoir (8 of 11 years sampled; 1993-2011).

**Overall Presence/Absence Patterns**

After combining presence/absence data for all rotenone and electrofishing sampling years (1947-2012), *L. auritus* was found in 11.8% of all sampling years in Kentucky, 25.8% in Pickwick, 16% in Wilson, 27.1% in Wheeler, 43.5% in Guntersville, 69.6% in Nickajack, 65.5% in Chickamauga, 82.8% in Watts Bar, and 75% in Fort Loudoun mainstem reservoirs (Figure 2).

**Sunfish Population Trends**

**Kentucky-Pickwick**

*Historical Patterns*

Rotenone samples (1949-1982) indicated that *L. auritus* was not found in the Kentucky-Pickwick River section; therefore regression methods were not applied to *L. auritus*. During 1949-1963, percent abundance (arcsin√p) of *L. megalotis* exhibited an increasing linear trend (P =
0.0031), while in 1971-1982 *L. megalotis* exhibited an increasing quadratic trend (P = 0.0215; Table 2, Figure 3). Density [Log$_{10}$ (fish/ha + 1)] and biomass [Log$_{10}$ (kg/ha + 1)] of *L. megalotis* (1971-1982) also exhibited increasing quadratic trends (P = 0.0127, P = 0.0036, respectively; Table 2, Figure 3).

For percent abundance, *L. macrochirus* exhibited a U-shaped quadratic pattern in 1949-1963 (P = 0.0126) and then a decreasing linear trend in 1971-1982 (P <0.0001). *L. macrochirus* demonstrated a fluctuating cubic pattern for density (P = 0.0311) and a quartic pattern for biomass (P = 0.0036; Table 2). *L. microlophus* percent abundance showed a cubic trend in 1949-1963 (P = 0.0142) and an increasing linear trend in 1971-1982 (P = 0.0020). *L. microlophus* also showed an increasing linear trend for both density and biomass (P <0.0001, P <0.0001 respectively; Table 2).

For *Lepomis* species composition during the four historical time periods (1950-1987), *L. megalotis* was consistently the second most abundant *Lepomis* species in Kentucky-Pickwick section, ranging from 25-35% in mean percent abundance (behind *L. macrochirus*; 49-63%; Figure 5).

**Contemporary Trends**

Electrofishing samples (1993-2011) indicated that *L. auritus* was present by 2001 in the Kentucky-Pickwick section; however, a significant population trend was not detected (percent abundance, CPUE; Table 3, Figure 4). For percent abundance, *L. megalotis* exhibited a dome-shaped quadratic trend (highest percent abundance occurred in the early 2000s; P = 0.0119); however, *L. megalotis* CPUE exhibited an increasing linear trend (P = 0.0011; Table 3, Figure 4).
L. macrochirus exhibited a dome-shaped quadratic pattern for percent abundance (P = 0.0028) and a fluctuating quartic pattern for CPUE (P = 0.0003; Table 3). L. microlophus showed a cubic trend for percent abundance (P = 0.0607) and an increasing linear trend for CPUE (P <0.0001; Table 3).

For Lepomis species composition during the two contemporary time periods (1993-2001, 2002-2011), L. megalotis was the most abundant species (mean percent abundance 49 % for both periods; Figure 5). L. auritus was not detected in Kentucky-Pickwick until 2001, and its mean percent abundance was 0.02% during 1993-2001 and 0.41% during 2002-2011.

Wilson-Wheeler

Historical Trends

Rotenone samples (1949-1997) indicated that L. auritus was present only three years (1950, 1984, and 1995) in Wilson-Wheeler River section; therefore regression methods were not applied to L. auritus. L. megalotis percent abundance exhibited a fluctuating cubic pattern with a generally increasing trend in 1949-1962 (P = 0.0259) and a decreasing linear trend in 1970-1997 (P <0.0001; Table 4, Figure 6). For density and biomass (1970-1997), L. megalotis exhibited a decreasing quadratic pattern (P <0.0001, P <0.0001 respectively; Table 4, Figure 6).

L. macrochirus did not exhibit a significant trend for percent abundance in 1949-1963, but showed an increasing linear trend in 1971-1982 (P <0.0001). Also, L. macrochirus exhibited a U-shaped quadratic trend for density (P = 0.0004) and biomass (P = 0.0302; Table 4). For percent abundance, L. microlophus showed an increasing linear trend for both time periods (P <0.0001, P = 0.0314 respectively), a fluctuating cubic trend for density (P = 0.0010), and an increasing quadratic trend for biomass (P = 0.0006; Table 4).
For *Lepomis* species composition during the five historical time periods (1950-1997), there was no statistical difference in the mean percent abundance of *L. megalotis* with other *Lepomis* species in 1950-59. However, *L. megalotis* was the second most abundant species (mean percent abundance 19-33%) during all other time periods (1960-1969, 1970-1979, 1980-1989, and 1990-1997) with the exception of *L. microlophus* in 1990-1997 (Figure 8). *L. auritus* mean percent abundance remained <1% for all time periods.

**Contemporary Trends**

Electrofishing samples (1993-2011) indicated that *L. auritus* was found consistently in Wilson-Wheeler River section; however, a significant population trend was not detected (percent abundance, CPUE; Table 5, Figure 7). For *L. megalotis*, both percent abundance and CPUE showed a fluctuating cubic pattern (P = 0.0015, P <0.0001 respectively; Table 5, Figure 7).

*L. macrochirus* exhibited a decreasing linear trend for percent abundance (P = 0.0020) and a quadratic trend with an increasing parabolic curve for CPUE (P <0.0001; Table 5). *L. microlophus* showed a quadratic trend for percent abundance (P = 0.0286) and fluctuating cubic pattern for CPUE (P = 0.0017; Table 5).

During the two contemporary time periods (1993-2001, 2002-2011), *L. megalotis* was the second most abundant taxa (mean percent abundance ranged from 28-35%) and was statistically different from all other *Lepomis* species (with the exception of *L. microlophus* during 1993-2001). *L. auritus* mean percent abundance remained <1% for all time periods (Figure 8).
Guntersville

Historical Trends

Rotenone samples (1949-1993) indicated that *L. auritus* was not consistently found until the early 1990s in Guntersville River section; therefore regression methods were not applied to *L. auritus*. Although there was no significant pattern in percent abundance for *L. megalotis* in 1949-1961, there was a decreasing linear pattern in 1971-1993 (*P* = 0.005; Table 6, Figure 9). It is also important to note that percent abundance of *L. megalotis* was more variable in 1949-1961 with relatively few zero data across sites/years, which contrasted with large amounts of zero data across sites/years in 1971-1993. *L. megalotis* exhibited a fluctuating cubic pattern with a generally decreasing trend for both density (*P* = 0.0030) and biomass (*P* = 0.0004) in 1971-1993 (Table 6, Figure 9). Furthermore, once *L. auritus* became established in the 1990s, density and biomass of *L. auritus* and *L. megalotis* appeared to be fairly similar.

Percent abundance of *L. macrochirus* demonstrated a cubic pattern in 1949-1961 (*P* = 0.0437) and then an increasing linear trend in 1971-1993 (*P* = 0.0738). For density and biomass, *L. macrochirus* demonstrated a fluctuating quartic trend (*P* = 0.0022, *P* = 0.0030 respectively; Table 6). For *L. microlophus*, there were no significant trends for percent abundance during either time period, while it showed a fluctuating quartic pattern for density and biomass (*P* = 0.0205, *P* = 0.0076 respectively; Table 6).

*Lepomis* species composition during the four historical time periods (1950-1993) indicated that *L. megalotis* was the second most abundant species from 1950-1961 (mean percent abundance was 12%) and statistically different from all other *Lepomis* species. However, beginning in the 1971-1979 time period, *L. microlophus* became more abundant than *L. megalotis* (*L. megalotis* was statistically different from *L. microlophus* only). This trend
continued in the 1980-88 and 1990-93 time periods (*L. megalotis* mean percent abundance ranged from 0.02-3% from 1971-1993; Figure 10). *L. auritus* mean percent abundance remained <2% during all time periods (1950-1993), but began increasing in abundance in the 1990s.

**Contemporary Trends**

Electrofishing samples (1993-2011) indicated that *L. auritus* was found consistently throughout sampling years in Guntersville River section, however; a significant population trend was not detected for percent abundance (Table 7, Figure 11). On the other hand, *L. auritus* density exhibited a fluctuating cubic pattern with a generally decreasing trend (*P* = 0.0011; Table 7, Figure 10). *L. megalotis* percent abundance showed a generally decreasing quartic trend (*P* = 0.0123) while its density showed a quartic pattern with a generally increasing trend (*P* = 0.026; Table 7, Figure 10). For both *L. macrochirus* and *L. microlophus*, there were no significant patterns for percent abundance, but density of both showed a generally increasing cubic trend (*P* = 0.0002, *P* = 0.0003 respectively; Table 7).

*Lepomis* species composition was generally similar during the two contemporary time periods (1993-2001, 2002-2011). For both time periods, *L. megalotis* mean percent abundance (12%, 8% respectively) was not statistically different from *L. auritus* (15%, 11%), more abundant than *L. cyanellus* (1%) and *L. gulosus* (8%, 4%), and less abundant than *L. macrochirus* (51%, 55%). *L. megalotis* was not statistically different from *L. microlophus* in 1993-2001 but became was less abundant than *L. microlophus* (21%) in 2002-2011.
Nickajack-Chickamauga

*Historical Trends*

Rotenone samples (1947-1997) revealed that *L. auritus* was not detected in Nickajack-Chickamauga River section until the 1970s, therefore regression methods were not applied to the 1947-1964 time period for *L. auritus* percent abundance. In 1970-1997, *L. auritus* exhibited an increasing linear trend for percent abundance ($P = 0.0006$), density ($P < 0.0001$), and biomass ($P < 0.0001$; Table 8, Figure 12). In contrast, *L. megalotis* demonstrated a decreasing linear trend for percent abundance ($P = 0.0001$), density ($P = 0.0017$), and biomass ($P = 0.0001$) in 1970-1997 (Table 8, Figure 12). There was no significant pattern for *L. megalotis* percent abundance in 1947-1964. It is also important to note that percent abundance of *L. megalotis* was more variable in 1947-1964 with relatively few zero data across sites/years, which contrasted with large amounts of zero data across sites/years in 1970-1997. Furthermore, once *L. auritus* became established in the late 1970s, density and biomass of *L. auritus* and *L. megalotis* appeared to be fairly similar.

For percent abundance, *L. macrochirus* demonstrated a decreasing linear trend in 1947-1964 ($P = 0.0098$) and a quadratic trend from 1970-1997 ($P = 0.0761$). However, *L. macrochirus* density and biomass (1970-1997) exhibited an increasing linear trend ($P < 0.0001$, $P = 0.0009$ respectively; Table 8). *L. microlophus* percent abundance exhibited an increasing linear trend for both time periods ($P = 0.0023$, $P < 0.0001$ respectively), and density and biomass also exhibited increasing linear trends ($P < 0.0001$, $P < 0.0001$; Table 8).

During the four historical time periods (1950-1997), there was a shift in species composition of *L. auritus*, *L. megalotis*, and *L. microlophus* (Figure 14). In 1950-1964 and 1970-1979, mean percent abundance of *L. megalotis* (8-14%) was greater than *L. auritus* (0-1%) and
L. cyanellus (<1%) and was equal to L. microlophus (10-16%). In 1980-1989 and 1990-1997, mean abundance of L. megalotis (1-3%) was equal to L. auritus (~3%) and less than L. microlophus (16-18%). Mean percent abundance of L. megalotis was consistently less than that of L. macrochirus (52-73%), which appeared to be the dominant species. Although L. megalotis (along with L. microlophus) appeared to be the second or third most abundant Lepomis species in 1950-1970s, few significant differences were detected between L. megalotis and other native species.

Contemporary Trends

Electrofishing samples (1993-2011) showed that both L. auritus and L. megalotis both showed a quadratic pattern with a generally increasing parabolic curve for percent abundance (P <0.0001, P = 0.0029 respectively) and an increasing linear trend for density (P <0.0001, P<0.0001 respectively; Table 9, Figure 13). L. macrochirus percent abundance and density showed a quadratic trend with a generally increasing parabolic curve (P = <0.0001, P <0.0001 respectively). L. microlophus percent abundance showed a fluctuating cubic pattern (P <0.0001), and density exhibited an increasing linear trend (P <0.0001; Table 9).

During the two contemporary time periods (1993-2001, 2002-2012), mean percent abundance of L. megalotis (6%, 9% respectively) was lower than that of L. auritus (16%, 26%) and L. macrochirus (49%, 42%), lower than or similar to that of L. microlophus (21%, 13%), and greater than or similar to that of L. cyanellus (3%, 5%) and L. gulosus (5%, 5%; Figure 14).
Watts Bar-Fort Loudoun

Historical Trends

Rotenone data indicate that *L. auritus* exhibited no significant change in percent abundance in 1949-1964 and showed a fluctuating cubic trend (P = 0.0045) in 1972-1988. For density and biomass (1972-1988), *L. auritus* exhibited a fluctuating cubic trend (P = 0.0038, P = 0.0467, respectively; Table 10, Figure 15). *L. megalotis* percent abundance showed a decreasing linear trend in 1949-1964 (P = 0.022) while exhibiting a dome-shaped quadratic trend in 1972-1988 (P = 0.0274). For density, *L. megalotis* showed a dome-shaped quadratic pattern (P = 0.0310; Table 10, Figure 15), but no significant trend was detected for biomass.

In comparison, *L. macrochirus* percent abundance showed a cubic pattern from 1949-1964 (P = 0.0842), and then a quadratic pattern in 1972-1988 (P = 0.0034); density and biomass demonstrated increasing quadratic trends (P = 0.0011, P = 0.0013, respectively; Table 10). *L. microlophus* percent abundance exhibited no significant pattern from 1949-1964 and showed an increasing linear trend in 1972-1988 (P = 0.0576); density and biomass also exhibited increasing linear trends (P = 0.0061, P = 0.0129, respectively; Table 10).

For *Lepomis* species composition during three historical time periods (1950-1964, 1972-1979, 1980-1988), mean abundance of LES (1-2 %) was less than or similar to that of RBS (3-8 %), less than that of BLG (84-86%), and similar to that of other Lepomis species (Figure 17).

Contemporary Trends

Electrofishing samples (1993-2011) from Watts Bar-Fort Loudoun indicated that both *L. auritus* and *L. megalotis* exhibited increasing linear trends for percent abundance (P = 0.0031, P = 0.0014, respectively) and density (P <0.0001, P <0.0001, respectively; Table 11, Figure 16). *L.
*macrochirus* exhibited a decreasing linear trend for percent abundance ($P < 0.0001$) and an increasing quartic trend for CPUE ($P = 0.0155$), whereas *L. microlophus* showed a fluctuating quartic trend for percent abundance ($P = 0.0247$) and an increasing linear trend for CPUE ($P < 0.0001$; Table 11).

*Lepomis* species composition was generally similar during two contemporary time periods (1993-2001, 2002-2012; Figure 17). Mean percent abundance of *L. megalotis* was statistically similar to that of *L. auritus* and *L. gulosus* and less than that of *L. macrochirus*, *L. cyanellus*, and *L. microlophus*. During 1993-2001, *L. auritus* and *L. megalotis* mean percent abundances were 6% and 1%, respectively, and were 8% and 7%, respectively, during 2002-2012.

Correlations Between Gear-Specific Estimates of Abundance

Linear relationships between estimates of electrofishing CPUE (catch [number of fish] per unit effort) and rotenone density (number of fish per ha) were detected for three of the four *Lepomis* species tested ($P \leq 0.05$ with a sequential Bonferroni adjustment; $n = 7$ reservoirs; reservoir-specific means were used in the analysis, 1993-1997). Electrofishing CPUE was directly related to rotenone density for *L. auritus* ($r = 0.805$, $P = 0.0290$), *L. megalotis* ($r = 0.806$, $P = 0.0287$), and *L. microlophus* ($r = 0.895$, $P = 0.007$), but not for *L. macrochirus* ($r = 0.142$, $P = 0.761$).
CHAPTER 4
DISCUSSION

Introduction of Redbreast Sunfish (*Lepomis auritus*) in the TRD

Historical rotenone data (1947-1997) suggest two major points of *L. auritus* entry into the TRD in the 1950s: 1) Fort Loudoun (1953)-Watts Bar (1957) in upper reaches 2) Wilson-Wheeler-Guntersville (1950 in each) in middle reaches. First records of *L. auritus* in the TRD (collected by TVA) dated back to the early 1940s in tributary streams of the upper TRD (TVA unpublished data). It appeared in 1940 in Clear Creek (Cocke County) and 1941 in Black Oak Branch just above the mouth of the Holston River (Jefferson County) as well as several additional streams in 1941 (Roane, Rhea, Grainger, Hamblen, and Loudoun counties; TVA unpublished data). Its first occurrence in the Tennessee River mainstem was approximately eight miles east-southeast of Fort Loudoun Dam in 1942 (TVA unpublished data). These data are generally consistent with sample data from Jenkins and Burkhead (1994), which states that first records of *L. auritus* in the South Fork of Holston River, a major tributary to the Tennessee River, occurred in 1956 in Boone Reservoir. Also, heavy stocking of *L. auritus* (approximately 19,000 fishes) occurred in the Clinch River in 1969 following a fish kill two years earlier (Jenkins and Burkhead 1994). In contrast, there are no known records of *L. auritus* stocking/collection in Wilson-Wheeler-Guntersville during or before the 1950s. First appearance of *L. auritus* in rotenone samples in mid-river sections occurred in the 1970s (Nickajack, 1972;
Chickamauga, 1976) and in the early 2000s in lower-western reaches (Pickwick, 2001; Kentucky, 2003). These occurrences may be related to additional sunfish stocking and/or dispersal from previous introductions.

Establishment of a species requires successful reproduction and overwintering in order to maintain a population (Moyle and Marchetti 2006, USGS 2013). Once a species is established in a particular location, spread of a population often indicates long-term persistence (Moyle and Marchetti 2006). Contemporary electrofishing (1993-2011) data indicate that L. auritus spread throughout most of the TRD by the early 2000s and was found consistently throughout the mainstem reservoirs thereafter; however, its abundance appears to vary along a longitudinal gradient.

Longitudinal Zonation in Geomorphology/Hydrology of the TRD

According to the River Continuum Concept, there is a natural and continuous physical gradient, or longitudinal zonation, along a river from its headwaters to the mouth (e.g., width, depth, velocity, temperature, cover, substrate and entropy gain; Vannote et al. 1980, Jenkins and Burkhead 1994). Headwater portions are characterized by high gradients and fast current velocities and may receive significant input of allochthonous detritus from riparian zones. Lower reaches closer to the mouth of a river are characterized by low gradient, meandering rivers that receive large amounts autochthonous materials such as fine particulate organic matter from decomposition upstream (Vannote et al. 1980). Headwater portions have generally harsher, less stable environmental conditions and typically support a low diversity of cool water fishes; in contrast, lower reaches tend to have more stable environmental conditions and support a more diverse collection of warm water fishes (Vannote et al. 1980).
Hydrological/morphological alterations such as impoundments and urbanization can often reset the continuum and create uncharacteristic conditions, depending on location and type of disturbance (Vannote et al. 1980, Ellis and Jones 2006). Based on the Serial Discontinuity Concept, impoundments alter geomorphology, water quality, temperature, and flow of river systems; consequently, these alterations have an impact on habitat and resource availability of lower trophic levels (e.g., macroinvertebrate and fish communities; Ellis and Jones 2006). However, when looking at such a broad scale as the TRD, there is still residual longitudinal zonation for some physical characteristics such as flow.

TVA mainstem impoundments are “flow-through” impoundments in which the downstream flow is generally maintained (Etnier and Starnes 1993). Therefore, even with presence of impoundments in the TRD, mean annual flow exhibits longitudinal zonation. In the upper reaches of the TRD, mean annual flow is generally lower (Fort Loudoun, 463 m$^3$/s; Watts Bar, 778 m$^3$/s) and tends to increase downstream. It ranges from 962 m$^3$/s in Chickamauga, 998 m$^3$/s in Nickajack, 1,172 m$^3$/s in Guntersville, 1,432 m$^3$/s in Wheeler, and 1,489 m$^3$/s in Wilson. In the lower reaches of the TRD, mean annual flow is generally highest (Pickwick, 1,573 m$^3$/s; Kentucky, 1,754 m$^3$/s; TVA 2004). Drainage area also shows evidence of longitudinal zonation, forming a gradient from the upper portions to lower portions of the TRD (24,730 mi$^2$, Fort Loudoun; 104,120 mi$^2$, Kentucky; TVA 2004). Furthermore, physiography progresses in a similar manner in terms of elevation. The upper reaches of the TRD are mostly within the Blue Ridge/Ridge and Valley ecoregions, which are characterized by higher elevations ($\leq$1500m) with varying peaks and valleys. The lower reaches of the TRD are within the Interior Plateau/Southeastern Plains, which are characterized by rolling plains and have lower elevations ($\leq$410m; EPA 2010).
Sunfish population parameters are interpreted within the context of the geomorphology, hydrology, and water chemistry that characterize three broad sections of the TRD (mainstem reservoirs in parentheses): lower-middle river (Kentucky-Pickwick-Wilson-Wheeler), middle-upper river (Guntersville-Nickajack-Chickamauga), and upper river (Watts Bar-Fort Loudoun).

Lower-Middle TRD

The lower-middle TRD (Kentucky-Pickwick-Wilson-Wheeler) is characterized by a more sinuous main channel and two large tributaries (Duck, Elk); most of the watershed drains the Southeastern Plains and Interior Plateau ecoregions (Figure 1).

In the Kentucky-Pickwick River section, data collections over a 62-year period (1949-2011) revealed that *L. megalotis* consistently was one of the two most abundant sunfish species (along with *L. macrochirus*). During different time periods before (1949-63; 1971-82) and during/after (1993-2011) the appearance of *L. auritus*, *L. megalotis* population parameters increased, increased and plateaued, or remained relatively stable. Following the first appearance of *L. auritus* in electrofishing samples in 2001, the species remained at very low levels for the next 10 years. Although *L. auritus* appeared in 1980 and 1984 rotenone samples from nearby Piney Creek (Pine Reservoir), the species was not found in rotenone samples collected in 1949-1987 in Kentucky Reservoir.

In the Wilson-Wheeler River section, data collections over a 62-year period (1949-2011) also revealed that *L. megalotis* consistently was one of the two most abundant sunfish species (along with *L. macrochirus*). *L. megalotis* generally decreased while other native congeners (*L. macrochirus* and *L. microlophus*) generally increased or exhibited no net change. Although *L. auritus* was first detected in Wilson-Wheeler in 1950, it was not found consistently until the

Watersheds of these reservoirs occupy portions of the Southeastern Plains and Interior Plateau ecoregions. Southeastern Plains streams/rivers typically have relatively low gradients and substrates of sand and silt/clay (Griffith et al. 1997). Interior Plateau streams (depending on sub-ecoregion) may have low to moderate gradients with sand-gravel substrates and areas of bedrock; collectively, this ecoregion supports the highest fish diversity in Tennessee (Etnier and Starnes 1993; Griffith et al. 1997).

Limnological conditions that characterize much of the lower TRD (low-moderate gradients, extensive littoral habitat) appear favorable for supporting *L. megalotis* populations, which may explain the dominance of this species in Kentucky-Pickwick River section. These favorable characteristics appear to decrease upstream, which may explain why *L. megalotis* is still abundant but does not thrive as well in Wilson-Wheeler section. *L. megalotis* populations have been reported do best in warm water habitats such as sluggish rivers with backwaters, pools, and other lentic habitats (Jenkins and Burkhead 1994), while *L. auritus* appear to prefer lotic conditions with higher flow (Sammons and Maceina 2009). Robust *L. megalotis* populations coupled with more suitable habitat and higher species diversity in these sections may give *L. megalotis* competitive edge over *L. auritus*.

Middle-Upper TRD

The middle-upper TRD (Guntersville-Nickajack-Chickamauga) is characterized by a more linear main channel; the river proper and most of the watershed drain portions the Southwestern Appalachians and Ridge and Valley ecoregions, with some influence from the Blue Ridge ecoregion (Figure 1).
In the Guntersville River section, data collections over a 62-year period (1949-2011) revealed that *L. megalotis* decreased from being one of the two most abundant species (along with *L. macrochirus*) in the 1950s, to being surpassed by a native congener (*L. microlophus*) by the 1990s. This trend appears to coincide with the presence of *L. auritus*. Throughout the 62-year period, *L. megalotis* abundance generally decreased while other native congeners (*L. macrochirus* and *L. microlophus*) generally increased or exhibited no net change. Although *L. auritus* was first detected in 1950, it was not detected again until the 1990s.

In the Nickajack-Chickamauga River section, data collections over a 65-year period (1947-2011) revealed that *L. auritus* was not detected in Nickajack-Chickamauga River section until the 1970s but significantly increased thereafter. Historical data (1947-1997) show that *L. auritus* had a linear increase in abundance, while *L. megalotis* exhibited a linear decrease. *L. megalotis* was the only native congeneric species that demonstrated a decreasing abundance in areas where *L. auritus* exhibited an increasing abundance from 1947-1997. Furthermore, *L. megalotis* abundance was surpassed by *L. auritus* in the 1990s and remained below *L. auritus* thereafter. *L. microlophus* exhibited a notable increase and was more abundant than *L. megalotis* in the 1980s-1990s, which coincided with increases in *L. auritus* abundance. In 1993-2011, all native *Lepomis* species and nonnative *L. auritus* generally increased. Overall, *Lepomis* species composition has shifted from 1947-2011.

Watersheds of these reservoirs mainly occupy portions of the Southwestern Appalachians and the Ridge and Valley ecoregions, with tributaries of Chickamauga draining the Blue Ridge ecoregion. The Southwestern Appalachians and Ridge and Valley ecoregions have similar topographical characteristics and contain streams of moderate to low gradient (Griffith *et al.* 1997). The Southwestern Appalachians contain low mountains, forests, and some pasture (EPA
However, limestone, coal, and iron deposits have resulted in significant historical mining activity in this ecoregion (Sohl 2012b). The Ridge and Valley contains low-lying valleys with parallel ridges, forests, and pastures (Friesen and Stier 2012). Extreme faulting and folding events within the Ridge and Valley resulted in complex geological regions composed of limestone, dolomite, shale, siltstone, sandstone, chert, mudstone, and marble (EPA 2010). Underlying geology can have a significant impact on the water chemistry of water bodies (Wooten et al. 1999). Many rivers within these sections have cut down into limestone strata of the Ridge and Valley, thus river water chemistry is more typical of Ridge and Valley. Limestone/dolomite dominated formations permit basic conditions (higher pH) and higher alkalinity (acid neutralizing capacity; Mosher et al. 2010).

Limnological conditions of Guntersville and Nickajack-Chickamauga River sections are characterized by a more linear channel morphology, moderate to low gradients with moderate flow (962-1,172 m$^3$/s). Nickajack-Chickamauga also have lower water residency times (WRT; 3-8 days), which creates a more riverine environment. High abundance and fast population growth of *L. auritus* in this Nickajack-Chickamauga River section may be related in part to reported preference of *L. auritus* for lower gradients, increased flows, and more lotic conditions (Aho et al. 1986, Jenkins and Burkhead 1994, Sammons and Maceina 2009). Conversely, this may not be optimal habitat for *L. megalotis*, giving *L. auritus* competitive edge in the middle-upper section of the TRD.

Upper TRD

The upper TRD (Watts Bar-Fort Loudoun) is characterized by a more dendritic main channel with four major tributaries (Clinch, Holston, French Broad, Little Tennessee rivers);
most the watershed drains Ridge and Valley and Blue Ridge ecoregions, with some influence from the Southwestern Appalachians ecoregion (mostly Cumberland Plateau portions; Figure 1).

Data collected from a 63-year period (1949-2012) in Watts Bar-Fort Loudoun River section revealed that *L. auritus* and *L. megalotis* were sympatric for most sampling years, and both species remained in relatively low abundances (< 10% of total *Lepomis* abundance); also, *L. auritus* was first detected in the 1950s and was consistently found in Watts Bar-Fort Loudoun River section thereafter, but it never significantly increased. Aside from a decreasing linear trend in percent abundance 1949-1964, *L. megalotis* showed no significant increases or decreases in all other population parameters 1949-1993. *L. auritus* abundance fluctuated and exhibited no net change. Both species generally increased 1993-2011 along with other native congeners (*L. macrochirus* and *L. microlophus*). Even in the years before *L. auritus* was present, *L. megalotis* exhibited low/sporadic abundance patterns.

Watersheds of these reservoirs mainly occupy portions of the Ridge and Valley and Blue Ridge ecoregions, containing smaller headwater streams with higher gradients (Griffith *et al.* 1997). The terrain of the Blue Ridge is characterized by narrow ridges and hilly plateaus, with elevations generally ranging from 300-1500m (EPA 2010). This part of TRD is mainly influenced by naturally soft, slightly acidic tributaries of Blue Ridge and the Cumberland Plateau portion of the Southwestern Appalachians ecoregions; these areas have low acid neutralizing capacity and thus have more pronounced impacts from acid pollution (low pH; Jenkins and Burkhead 1994).

Limnological conditions of Watts Bar-Fort Loudoun River section appear to be less suitable for both *L. auritus* and *L. megalotis*. Higher gradients in upper TRD are considered low quality sunfish habitat. For instance, *L. auritus* is more abundant in low gradient (<2m/km)
streams/rivers (Aho et al. 1986), and L. megalotis tends to avoid the higher gradient streams in the Blue Ridge and Ridge and Valley ecoregions of the upper TRD (Jenkins and Burkhead 1994). Also, fish diversity is naturally inversely correlated with stream gradient and tends to be lower in headwaters where harsher environmental conditions tend to prevail (Vannote et al. 1980). In addition to steep gradients, L. auritus appears to be an acid intolerant species, which may explain its low abundances in naturally acidic areas of the Blue Ridge (Jenkins and Burkhead 1994, Schorr and Baker 2006). Flow may also play a role in the difference between the two river sections. L. auritus experiences greater growth in rivers of higher flow/more rainfall (Sammons and Maceina 2009). However, Watts Bar-Fort Loudoun River section has lower mean annual flow (463-778 m$^3$/s) and a higher WRT (10-17 days).

Water pollution has been a longstanding issue within Watts Bar and Fort Loudoun river systems, which may further explain low abundances for both species. The upper Holston and lower Watauga river systems have experienced extensive pollution, mainly due to paper-mill effluents; the Clinch and Powell river systems have received heavy siltation from strip mines near headwaters in the coal regions of Virginia (Etnier and Starnes 1993).

Factors Influencing Nonnative Impacts

The abundance of a particular species typically operates in a fluctuating cyclic pattern with no significant net change over an extended period of time (Maes et. al 2005, Saito et al. 2012). In the present study, L. megalotis was the only native congeneric species (of the three native species examined) that demonstrated a decreasing abundance in areas where L. auritus exhibited an increasing abundance over time: Nickajack-Chickamauga River section (with the exception of electrofishing samples, 1993-2011).
One explanation is that *L. auritus* and *L. megalotis* have similar ecological preferences, which increase competitive interactions between sympatric populations (Cooner and Bayne 1982, Etnier and Starnes 1993). A study by Cooner and Bayne (1982) in the Tallapoosa River drainage in Alabama found that both species are insectivores, and using the Schoener Index, found that their diets significantly overlapped and appeared similar enough to possibly influence the distribution of *L. auritus* and *L. megalotis*. Nonnative species of similar trophic levels enhance interspecific competition, and native species are often displaced as a result (Gozlan *et al.* 2010). A study by Vander Zanden *et al.* (1999) found that Lake Trout (*Salvelinus namaycush*) relied primarily on littoral prey fishes in lakes without introduced Smallmouth Bass (*Micropterus dolomeiu*) and depended on zooplankton where they are sympatric with *M. dolomeiu*, which shows that *M. dolomeiu* has caused lake trout to shift to a less suitable trophic niche. However, it is important to note that *L. auritus* and *L. megalotis* both consume a wide variety of organisms based on prey availability (Cooner and Bayne 1982), and other *Lepomis* species have been shown to exhibit shifts in feeding behavior and prey items when competition is present (VanderKooy *et al.* 2000).

Habitat preference may play a role as there is evidence of native species shifting habitat use in the presence of a nonnative fish species (Cucherousset and Olden 2011). Although *L. auritus* exploits a variety of ecological conditions, both species prefer rocky/sandy pool habitat in shallow littoral areas (Aho *et al.* 1986). In a similar study by Marchetti (1999), the Sacramento Perch (*Archoplites interruptus*) altered its habitat use in the presence of the introduced and aggressively dominant Bluegill Sunfish (*Lepomis macrochirus*), which was also associated with a decrease in its growth rate due to interspecific competition (Marchetti 1999).
L. auritus and L. megalotis also have very similar spawning habitat along shorelines in gravel/sandy substrate near cover; spawning temperatures also overlap (Dupuis and Keenleyside 1988, Etnier and Starnes 1993, Boschung and Mayden 2004). At study by Ayala et al. (2007) in Utah found that populations of the native Least Chub (Lotichthys phelgethontis) declined following the introduction of the Western Mosquitofish (Gambusia affinis) due to habitat degradation and overlapping spawning habitat.

L. megalotis is listed as an intolerant species and is susceptible to water quality degradation (Jennings 2013, TVA unpublished data), which may further explain why it is more impacted by L. auritus than other congeners. Furthermore, L. megalotis is known to have a very small home range, thus may be more easily impacted by local conditions (e.g., water quality, interspecific competition; Gerking 1953, Etnier and Starnes, 1993). Johnston and Smithson (2000) found that L. megalotis remained in home pools, whereas L. auritus often moved approximately 16 km from its release site (Hudson and Hester 1976). L. auritus tends to grow faster and to larger sizes than L. megalotis, which may allow L. auritus to outcompete L. megalotis for ideal habitat and foraging opportunities (Etnier and Starnes 1993). A study by Winston (1995) found that interspecific competition resulted in a significantly low degree of co-occurrence of morphologically similar cyprinid species within in the central United States. Overall, significant overlap of ecological preferences and differences in tolerances are probable explanations to declines of L. megalotis where L. auritus is increasing/maintains high abundance.

Factors Influencing Species Abundance/Distribution

Fish distribution is significantly related to an assemblage of water quality conditions and geographic variables that operate in a multivariate manner (Matthews and Robison 1988,
Matthews et al. 1992). Furthermore, local fish assemblages are usually immediate products of contemporary and local processes, but regional and historical impacts can also be significant (Tonn et al. 1990). Water quality parameters that impact fish distribution and community composition include salinity, pH, temperature, and dissolved oxygen, hardness, alkalinity, total dissolved solids, chloride, and ammonia; geological variables include elevation, precipitation, groundwater inflow, and morphological features (e.g., vegetative cover, substrate types, and depth) as well as anthropogenic influences (e.g. historical and current land use, altered flow/impoundments; Matthews and Robison 1988, Matthews et al. 1992, Persson 1996, Jackson et al. 2001, Marchetti and Moyle 2001, Bunn and Arthington 2002, Wenger et al. 2008).

*L. megalotis* is considered intolerant of water quality degradation and has been used as an indicator of good stream health (Jennings 2013). Water pollution issues in tributaries of/within Watts Bar-Fort Loudoun River section have impacted its water quality (Etnier and Starnes 1993), and consequently has consistently received low (poor-fair) ecological health ratings (1994-2011). Wilson-Wheeler River section also has consistently low (poor-fair) ecological health ratings, whereas Kentucky-Pickwick received fair-good ecological health ratings (1993-2011). This likely contributed to high fish diversity and strong *L. megalotis* populations in Kentucky-Pickwick River section.

Land use via human disturbance (e.g., urbanization, agriculture, impoundments), which is linked to the expansion of nonnative fishes, may play a role in differences between river sections (Marchetti and Moyle 2001, Bunn and Arthington 2002, Wenger et al. 2008). Human disturbance creates new lacustrine habitats and a high degree of disruption of natural characteristics (e.g., reservoirs, altered flow regimes), which favor alien species (Moyle and Marchetti 2006). Another study by Wenger et al. (2008) examined stream fish occurrence in the
Etowah River basin in Georgia and found that current effective impervious cover and historic land use were predictor variables for four of five species examined.

Biotic factors such as interspecific competition and predation also have the capacity to play an important role in the organization of local fish communities (Matthews and Robison 1988, Winston 1995, Jackson et al. 2001). A similar study conducted by Persson (1996) found that biotic factors such as interspecific competition and predation were the main factors impacting perch populations, whereas abiotic factors such as conductivity and pH played a lesser role. Moreover, Gatz (1979) found that percentage of overlap in coexisting species is half as much in nature compared to the amount of overlap possible; this pattern could be due to competition between species, forcing them into separate ecological niches. *L. auritus* and *L. megalotis* are closely related and have similar ecological preferences (i.e., diet overlap, habitat preference, and spawning conditions), which increase competitive interactions between sympatric populations (Cooner and Bayne 1982, Etnier and Starnes 1993).

Prevalence and success of nonnative fish introductions is also often correlated with low native species diversity (Gido and Brown 1999, Tsunoda and Mitsuo 2012), whereas nonnative fish impacts are minimized by higher native species diversity (Carey and Wahl 2010). Carey and Wahl (2010) found that although the introduced Common Carp (*Cyprinus carpio*) reduced resources for native species, higher native diversity (species richness) mitigated the impacts of *C. carpio*. The highest fish species diversity in Tennessee occurs in the Interior Plateau ecoregion, which contains portions of Kentucky-Pickwick River section and its watersheds where *L. auritus* remains in low abundance. Alternatively, upper portions of the TRD are naturally low in fish species diversity. Also, river sections may differ in degrees of saturation of fish species, which may be a contributing factor in the ability of *L. auritus* to proliferate in certain areas. For
instance, nonnative species are more likely to become established in a local community if the community is unsaturated (Smith et al. 2004).

Relationship Between Estimates of Rotenone and Electrofishing Abundance

Pearson’s linear correlation analysis examined density correlations between overlapping years of historical rotenone (1947-1997) and contemporary electrofishing (1993-2011) samples in order to determine if electrofishing CPUE was an accurate index of *Lepomis* density. The results indicated a significant positive correlation between two datasets in three of the four *Lepomis* species examined. This suggests that sampling procedures (rotenone vs. electrofishing) yielded similar results in determining density.

A similar study by Tate et al. (2003) found that electrofishing resulted in capture of larger sizes of Largemouth Bass (*Micropterus salmoides*) than rotenone sampling. Overall, Tate et al. (2003) determined that electrofishing was a precise and cost-effective method for estimating *M. salmoides* abundance. Knight and Cooper (2008) compared rotenone and electrofishing sampling methods in four stream reaches and found no significant difference between predicted and observed number of fish during electrofishing; however, fish biomass was underestimated during 15-minute run intervals and would be most accurate with 30-minute run intervals. TVA electrofishing methods for data used in this study included sampling runs ranging from 10-30 minutes. Although we cannot assume that the electrofishing data is an extension of rotenone data, the data exhibited the same general trends, sampled similar habitats (shoreline, littoral zone), and is supported by similar studies.
Future Research

Further studies are needed in order to fully understand the impacts and interactions of *L. auritus* with native congeners as well as other native fishes in the TRD. First, Pearson’s linear correlation analysis could be used to test relationships between *L. auritus* abundance and native sunfish abundance/diversity, and between sunfish and environmental parameters (e.g., geological variables, land use, and water quality). This analysis will examine factors that may influence the spatial distribution and abundance of *L. auritus* and native sunfish populations within various ecoregions, which may help identify areas of concern. Furthermore, using Principle Components Analysis (PCA) or another multivariate ordination method could provide overall summaries of *Lepomis* assemblage composition/structure across spatial (groups of reservoirs) and temporal (years before and after *L. auritus*) scales.

Analysis of additional TVA data from the Index of Biological Integrity (IBI) surveys (1993-2012) would provide a more accurate understanding of the current status of *Lepomis* species in the TRD and extend that knowledge into smaller streams. Furthermore, suitable habitat of *L. megalotis* could be mapped, which would allow for comparison of percentage of suitable habitat versus actual spatial distribution. Lastly, conducting competition studies through mesocosm experiments between *L. auritus*, *L. megalotis*, and other native fish taxa will provide direct statistical evidence of *L. auritus* impacts on native fish taxa. Knowledge obtained from this study and future studies will be vital in protecting native species such as *L. megalotis* and preserving biodiversity in the TRD.
Conclusions

*L. auritus* was introduced into the upper portions of TRD in the early 1940s by intentional stocking. Historical rotenone data (1947-1997) suggest two major points of *L. auritus* entry into the TRD in the 1950s: 1) Fort Loudoun (1953)-Watts Bar (1957) in upper reaches 2) Wilson-Wheeler-Guntersville (1950 in each) in middle reaches. *L. auritus* is now well established throughout most of the TRD and may produce more impacts in the future (e.g., Kentucky-Pickwick River section, where it is likely to increase in abundance). However, *L. auritus* appears to thrive mainly in low gradient lotic river sections with moderate flow/low WRT (i.e., Nickajack-Chickamauga) and remains in low abundances in higher gradient sections or areas with low flow/highWRT.

*L. auritus* correlation with native congeneric sunfishes varied. It did not significantly impact the abundance of *L. macrochirus* and *L. microlophus* in any river section; however, *L. megalotis* abundance declined in reservoirs where *L. auritus* was found to be in high/increasing abundance, and was particularly impacted in Nickajack-Chickamauga River section. *L. megalotis* consistently remained one of the two most abundant *Lepomis* species in the Lower-Middle TRD (Kentucky-Pickwick-Wilson-Wheeler). However, *L. auritus* abundance surpassed *L. megalotis* in portions of the middle-upper reaches of the TRD (Nickajack-Chickamauga). Both species remained in low abundances in upper reaches of the TRD (Watts Bar-Fort Loudoun). Although it is difficult to isolate causal variables and determine exactly which biotic and abiotic factors are influencing these trends, there is substantial evidence that *L. auritus* is negatively impacting *L. megalotis* and altering *Lepomis* species composition in Nickajack-Chickamauga River section and possibly in Guntersville River section. The interaction of both biotic (i.e., *L. auritus* competition) and abiotic (i.e., ecoregion, water quality, flow) factors likely explain the changes
in *L. megalotis* abundance, shifting *Lepomis* species composition, and variability within river sections. It is also likely that the full impact of *L. auritus* has not been seen because nonnative species can take considerable time to become established and to see evidence of impacts (≥100 years; Smith *et al.* 2004).

Quantifying the distribution and abundance of an introduced fish species and native congeneric species in an aquatic system is an important first step to understanding and studying its possible interactions and effects of nonnative species on native species. These spatiotemporal patterns provide a better understanding of the current status of nonnative *L. auritus* as well as native congeneric sunfishes.

Arcsin percent abundance (arcsin√p)

Years

**Longear Sunfish**

1949-63:  
\[ \hat{y} = 0.02648 + 0.01562x \]

\[ P = 0.0031 \]

1971-82:  
\[ \hat{y} = -10.6159 + 0.5883x - 0.00781x^2 \]

\[ P = 0.0215 \]

\[ \hat{y} = -4.6981 + 0.7764x - 0.02154x^2 \]

\[ P = 0.0127 \]

\[ \hat{y} = -3.5110 + 0.4874x - 0.01348x^2 \]

\[ P = 0.0036 \]

Figure 3  
Arcsine-transformed percent abundance (arcsin square root of species proportion \[p_i\], where \[p_i\] = number of individuals of a species / total number of individuals of all *Lepomis* sunfishes) and log-transformed density [log\(_{10} \) (fish/ha + 1), log\(_{10} \) (kg/ha + 1)] of *Lepomis auritus* (Redbreast Sunfish) and *L. megalotis* (Longear Sunfish) in rotenone samples (1949-1982) from Kentucky-Pickwick section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\(P \leq 0.05\), with Bonferroni adjustment).
Figure 4  Arcsine-transformed percent abundance (arcsin square root of species proportion \(p_i\), where \(p_i = \text{number of individuals of a species} / \text{total number of individuals of all} \ Lepomis \ \text{sunfishes}\) and log-transformed density \(\log_{10}(\text{CPUE} + 1)\) of \(L. \ auritus\) (Redbreast Sunfish) and \(L. \ megalotis\) (Longear Sunfish) in electrofishing samples (1993-2011) from Kentucky-Pickwick section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\(P \leq 0.05\), with Bonferroni adjustment).
Figure 5  Sunfish species composition (% of total number of *Lepomis* spp.) in Kentucky-Pickwick River section during successive time periods (n = 4-10 years) of rotenone (1949-1982) and electrofishing (1993-2011) TVA datasets. Repeated-measures ANOVA and Dunnett’s test (*P < 0.05) compared mean arcsin % abundance of *L. megalotis* with other congeneric sunfishes. Asterisks indicate that means were different from *L. megalotis*. *L. macrochirus* (BLG) was the dominant species in rotenone data (means ranging 48.5-62.7) but is not presented in rotenone figures in order to enhance comparisons between other congeneric sunfishes.
Figure 6  Arcsine-transformed percent abundance (arcsin square root of species proportion $[p_i]$, where $p_i =$ number of individuals of a species / total number of individuals of all *Lepomis* sunfishes) and log-transformed density $[\log_{10}(\text{fish/ha} + 1), \log_{10}(\text{kg/ha} + 1)]$ of *Lepomis auritus* (Redbreast Sunfish) and *L. megalotis* (Longear Sunfish) in rotenone samples (1949-1997) from Wilson-Wheeler section of the Tennessee River; predicted curves are based on mixed-model regression analysis ($P \leq 0.05$, with Bonferroni adjustment).
Wilson-Wheeler River Section (TR km 418-562)
Electrofishing Data, 1993-2011

Figure 7 Arcsine-transformed percent abundance (arcsin square root of species proportion \[ p_i \], where \( p_i \) = number of individuals of a species / total number of individuals of all \( Lepomis \) sunfishes) and log-transformed density \([\log_{10}(CPUE + 1)]\) of \( L. auritus \) (Redbreast Sunfish) and \( L. megalotis \) (Longear Sunfish) in electrofishing samples (1993-2011) from Wilson-Wheeler section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\( P \leq 0.05 \), with Bonferroni adjustment).
Figure 8  Sunfish species composition (% of total number of *Lepomis* spp.) in Wilson-Wheeler River section during successive time periods (n = 4-10 years) of rotenone (1949-82) and electrofishing (1993-2011) TVA datasets. Repeated-measures ANOVA and Dunnett’s test (*P < 0.05) compared mean arcsin % abundance of *L. megalotis* with other congeneric sunfishes. Asterisks indicate that means were different from *L. megalotis*. *L. macrochirus* (BLG) was the dominant species (mean % abundances ranging 35.2-70.6) but is not presented in order to enhance comparisons between other congeneric sunfishes.
Figure 9  Arcsine-transformed percent abundance (arcsin square root of species proportion \[p_i\], where \[p_i\] = number of individuals of a species / total number of individuals of all \textit{Lepomis} sunfishes) and log transformed density [\(\log_{10}(\text{fish/ha + 1})\), \(\log_{10}(\text{kg/ha + 1})\)] of \textit{Lepomis auritus} (Redbreast Sunfish) and \textit{L. megalotis} (Longear Sunfish) in rotenone samples (1949-1993) from Guntersville section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\(P \leq 0.05\), with Bonferroni adjustment).
Figure 10  Arcsine-transformed percent abundance (arcsin square root of species proportion \(p_i\), where \(p_i\) = number of individuals of a species / total number of individuals of all *Lepomis* sunfishes) and log-transformed density \(\log_{10}(CPUE + 1)\) of *Lepomis auritus* (Redbreast Sunfish) and *L. megalotis* (Longear Sunfish) in electrofishing samples (1993-2011) from Guntersville section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\(P \leq 0.05\), with Bonferroni adjustment).
Figure 11  Sunfish species composition (% of total number of *Lepomis* spp.) in Guntersville River section during successive time periods (n = 7-10 years) of rotenone (1949-82) and electrofishing (1993-2011) TVA datasets. Repeated-measures ANOVA and Dunnett’s test (*P < 0.05) compared mean arcsin % abundance of *L. megalotis* with other congeneric sunfishes. Asterisks indicate that means were different from *L. megalotis*. *L. macrochirus* (BLG) was the dominant species (mean % abundances ranging 50.7-74.1) but is not presented in order to enhance comparisons between other congeneric sunfishes.
Figure 12  Arcsine-transformed percent abundance (arcsin square root of species proportion \([p_i]\), where \(p_i\) = number of individuals of a species / total number of individuals of all *Lepomis* sunfishes) and log transformed density \([\log_{10}(\text{fish/ha} + 1)\), \(\log_{10}(\text{kg/ha} + 1)\)] of *Lepomis auritus* (Redbreast Sunfish) and *L. megalotis* (Longear Sunfish) in rotenone samples (1949-1997) from Nickajack-Chickamauga section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\(P \leq 0.05\), with Bonferroni adjustment).
Figure 13  Arcsine-transformed percent abundance (arcsin √p<sub>i</sub>) and log-transformed density [log<sub>10</sub>(CPUE + 1)] of *Lepomis auritus* (Redbreast Sunfish) and *L. megalotis* (Longear Sunfish) in electrofishing samples (1993-2011) from Nickajack-Chickamauga section of the Tennessee River; predicted curves are based on mixed-model regression analysis (P ≤ 0.05, with Bonferroni adjustment).
Figure 14  Sunfish species composition (% of total number of *Lepomis* spp.) in Nickajack-Chickamauga River section during successive time periods (n = 10-12 years) of rotenone (1949-82) and electrofishing (1993-2011) TVA datasets. Repeated-measures ANOVA and Dunnett’s test (*P < 0.05) compared mean arcsin % abundance of *L. megalotis* with other congeneric sunfishes. Asterisks indicate that means were different from *L. megalotis*. *L. macrochirus* (BLG) was the dominant species (mean % abundances ranging 41.8-73.2) but is not presented in the figure in order to enhance comparisons between other congeneric sunfishes.
Figure 15  Arcsine-transformed percent abundance (arcsin square root of species proportion \( p_i \), where \( p_i \) = number of individuals of a species / total number of individuals of all \( Lepomis \) sunfishes) and log-transformed density \( \log_{10}(\text{fish/ha} + 1) \) and \( \log_{10}(\text{kg/ha} + 1) \) of \textit{Lepomis auritus} (Redbreast Sunfish) and \textit{L. megalotis} (Longear Sunfish) in rotenone samples (1949-1993) from Watts Bar-Fort Loudoun section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\( P \leq 0.05 \), with Bonferroni adjustment).
Figure 16  Arcsine-transformed percent abundance (arcsin square root of species proportion [\(p_i\)], where \(p_i\) = number of individuals of a species / total number of individuals of all Lepomis sunfishes) and log-transformed density [\(\log_{10}(\text{CPUE} + 1)\)] of Lepomis auritus (Redbreast Sunfish) and L. megalotis (Longear Sunfish) in electrofishing samples (1993-2011) from Watts Bar-Fort Loudoun section of the Tennessee River; predicted curves are based on mixed-model regression analysis (\(P \leq 0.05\), with Bonferroni adjustment).
Figure 17  Sunfish species composition (% of total number of *Lepomis* spp.) in Watts Bar-Fort Loudoun River section during successive time periods (n = 5-10 years) of rotenone (1949-88) and electrofishing (1993-2011) TVA datasets. Repeated-measures ANOVA and Dunnett’s test (*P < 0.05) compared mean arcsin % abundance of *L. megalotis* with other congeneric sunfishes. Asterisks indicate that means were different from *L. megalotis*. *L. macrochirus* (BLG) was the dominant species (mean % abundances ranging 45.0-85.7) but is not presented in the figure in order to enhance comparisons between other congeneric sunfishes.

a Kilometers (km) from the mouth of the Tennessee River at location of impoundment.
APPENDIX B

DENSITY (FISH/HA) AND BIOMASS (KG/HA) OF *LEPOMIS* SPECIES COLLECTED BY
TVA COVE-ROTENONE SURVEYS (1947-1997) IN MAINSTEM AND SELECTED
TRIBUTARY RESERVOIRS IN THE TENNESSEE RIVER DRAINAGE
Appendix B.1  Density (fish/ha) of *L. auritus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.2  

Density (fish/ha) of *L. megalotis* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.3  
Density (fish/ha) of *L. macrochirus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.4  Density (fish/ha) of *L. cyanellus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Density (fish/ha) of *L. gulosus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.6  Density (fish/ha) of *L. microlophus* collected by TVA cove-rotene surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.7  Biomass (kg/ha) of *L. auritus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.8  Biomass (kg/ha) of *L. megalotis* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.9  Biomass (kg/ha) of *L. macrochirus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.10  Biomass (kg/ha) of *L. cyanellus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.11  Biomass (kg/ha) of *L. gulosus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
Appendix B.12  Biomass (kg/ha) of *L. microlophus* collected by TVA cove-rotenone surveys (1960-97) in mainstem and selected tributary reservoirs in the Tennessee River drainage. Data collected during or prior to 1960 is not suitable for quantitative analysis; therefore, only data occurring after 1960 is shown.
APPENDIX C

SUMMARY STATISTICS OF POPULATION PARAMETERS FOR *LEPOMIS* SPECIES
COLLECTED FROM TVA COVE-ROTHENONE SAMPLES (1949-1984) AND
ELECTROFISHING SAMPLES (1993-2011) IN KENTUCKY
RESERVOIR AND TRIBUTARY RESERVOIRS
Appendix C.1  Summary statistics for density (fish/ha) of *Lepomis* spp. in Kentucky Reservoir and tributary reservoirs collected from TVA cove-rotenone samples (1960-1984).

APPENDIX D
SUMMARY STATISTICS OF POPULATION PARAMETERS FOR *LEPOMIS* SPECIES
COLLECTED FROM TVA COVE-ROTENONE SAMPLES (1949-1987) AND
ELECTROFISHING SAMPLES (1993-2011) IN PICKWICK
RESERVOIR AND TRIBUTARY RESERVOIRS
Appendix D.1  Summary statistics for density (fish/ha) of *Lepomis* spp. collected from TVA cove-rotenone samples (1960-1987) in Pickwick Reservoir and tributary reservoirs in the Tennessee River drainage.

APPENDIX E

SUMMARY STATISTICS OF POPULATION PARAMETERS FOR *LEPOMIS* SPECIES

COLLECTED FROM TVA COVE-ROTHENONE SAMPLES (1949-1983) AND

ELECTROFISHING SAMPLES (1993-2011) IN WILSON RESERVOIR
Appendix E.1

Summary statistics for density (fish/ha) of *Lepomis* spp. collected from TVA cove-rotenone samples (1960-1983) in Wilson Reservoir and tributary reservoirs in the Tennessee River drainage.

APPENDIX K

SUMMARY STATISTICS OF POPULATION PARAMETERS FOR *LEPOMIS* SPECIES

COLLECTED FROM TVA COVE-ROTHENONE SAMPLES (1949-1994) AND
ELECTROFISHING SAMPLES (1993-2011) IN FORT LOUDOUN
RESERVOIR AND TRIBUTARY RESERVOIRS
Appendix K.1  Summary statistics for density (fish/ha) of *Lepomis* spp. collected from TVA cove-rotene samples (1961-1988) in Fort Loudoun mainstem and tributary reservoirs in the Tennessee River drainage.

VITA

Lacey M. Genard was born in Valley Grande, Alabama to Thomas M. Genard and Carla M. Pugh. She attended Dallas County High School and graduated Valedictorian in 2006. She then attended Birmingham-Southern College and received a Bachelor of Arts degree in Urban Environmental Studies with a Natural Science concentration. She graduated *Magna Cum Laude* and was a member of the Phi Beta Kappa Honor Society. She accepted research and later a teaching assistantship to attend the University of Tennessee at Chattanooga (UTC). She graduated from UTC with a Master of Science degree in May of 2014. She currently works as an environmental scientist in the Aquatic Assessment Unit of the Alabama Department of Environmental Management.
